(Received 14 February 2012; published 28 February 2012)

Phonon dispersions generically display nonanalytic points, known as Kohn anomalies, due to electron-phonon interactions. We analyze this phenomenon for a zone-boundary phonon in undoped graphene. When electron-electron interactions with coupling constant $\beta$ are taken into account, one observes behavior demonstrating that the electrons are in a critical phase: the phonon dispersion and lifetime develop power-law behavior with $\beta$-dependent exponents. The observation of this signature would allow experimental access to the critical properties of the electron state, and would provide a measure of its proximity to an excitonic insulating phase.

I. INTRODUCTION

The study of electron-electron interactions in graphene, a monolayer of carbon, remains one of the most interesting open problems in the field and is currently a very active area of research. The Coulomb interaction plays a very particular role in this system because its low-energy electronic excitations are described by massless Dirac fermions. For undoped graphene, the vanishing of the density of states at the Fermi level implies that the interaction remains truly long ranged, decaying in real space as $1/r$, and this is predicted to lead to a number of exotic interaction-induced phenomena, such as logarithmic renormalization of many physical observables at weak coupling and instabilities toward different symmetry-breaking states, like the excitonic insulator, at strong coupling. This suggests that Coulomb interactions can be relatively important, but experimentally their strength is still debated.

One of the most striking predicted effects of the Coulomb interaction in graphene is that, because the Hamiltonian describes it is scale invariant, some of its correlation functions behave like power laws with interaction-dependent exponents that are set to zero. The Coulomb interaction can be relatively important, but experimentally their strength is still debated.

The presence of these power laws can be understood in simple terms, while their detailed behavior requires an elaborate calculation discussed below. Consider the usual low-energy Hamiltonian for graphene around the $K$ and $K'$ points:

$$H = i \nu_F \int d^2r \psi^\dagger (\alpha_x \partial_x + \alpha_y \partial_y) \psi,$$

where $\alpha = (\tau, \sigma, \sigma_z)$, where the $\sigma$ and $\tau$ matrices act on the sublattice and valley degrees of freedom, respectively (spin will be accounted for when necessary). The chemical potential is set to zero. This Hamiltonian has an SU(2) valley symmetry generated by the matrices $T_i = (\tau_x, \tau_y, \tau_z)$, in the sense that the SU(2) rotation $\psi \rightarrow e^{i T_i f_i} \psi$ leaves the Hamiltonian invariant. When the Coulomb interaction

$$H_{\text{int}} = \frac{e^2}{2} \int d^2r d^2r' \frac{\psi_i^\dagger \psi_j \psi_i^\dagger \psi_j'}{|r - r'|}$$

is included, and for $\beta$ greater than some critical value $\beta_c$, this system has an instability to an ordered state known as the excitonic insulator, where charge imbalance between sublattices, i.e., an expectation value of $\psi_i^\dagger \sigma_z \psi_j$, develops. This instability is reflected in the corresponding susceptibility $\langle \psi_i^\dagger \sigma_z \psi_j^\dagger \sigma_z \psi_i \psi_j \rangle$ at $\omega = 0$, which develops a power law $q_{\text{int}}^\beta$ with an interaction-dependent exponent that goes to zero for $\beta \rightarrow \beta_c$, signaling the onset of the excitonic phase.

Therefore, power-law behavior in this correlator can be thought of as the weak-coupling counterpart of the excitonic instability, and experimental access to the exponent would allow one to probe how close the system is to it. However, this particular susceptibility is difficult to measure, as it requires a probe that couples differently to the two sublattices.

The charge density wave (CDW) instability is, however, not only the one that Coulomb interactions can induce. The Hamiltonian (1) admits two other time-reversal-invariant
masses $\tau_x\sigma_y$ and $\tau_y\sigma_x$, and an instability that develops an expectation value for either of them may proceed in the same way. These order parameters correspond to a bond density wave order known as the Kekulé distortion. It can be shown that the Kekulé and CDW masses $M_a = (\tau_x\sigma_y, \tau_y\sigma_x, \tau_x\sigma_y)$ transform like a spin-1/2 under the valley symmetry, and since the Coulomb interaction does not break this symmetry, the three instabilities are in fact equivalent: they have the same weak-coupling power-law susceptibility with the same exponents. Since, as we will see, the $A_1$ electron-phonon vertex corresponds to the Kekulé mass, the phonon self-energy is proportional to the Kekulé susceptibility. Therefore, we expect power-law behavior in the phonon dispersion and lifetime. To see this, however, the computation of the full $\omega$-dependent susceptibility is required. In the remainder of this paper, we discuss the electron-phonon coupling in graphene and the computation of the phonon self-energies with the aim of establishing precisely where the signatures of critical behavior are to be found.

II. PHONONS AND KOHN ANOMALIES

The phonon spectrum of the honeycomb lattice consists of six phonon branches, four in plane and two out of plane. Each of these phonons may couple to electrons near either Dirac point if it has momentum close to zero (a $\Gamma$ point or zone-center phonon), which scatters electrons within each valley, or if it has momentum close to $K$ or $K'$ points (a zone-boundary phonon), in which case it produces intervalley scattering. The strength of the electron-phonon coupling (EPC), however, depends on how the particular displacement pattern of that phonon modifies the hopping integrals between atoms. Two modes have displacements that produce a significant EPC. The first of these is the phonon branch of highest energy at the $\Gamma$ point, the $E_2$ phonon. The second is the $A_1$ branch at the $K$ and $K'$ points (also the highest branch). This is a lattice distortion with a supercell of six atoms, the displacement pattern of which is obtained by taking linear combinations of the displacements at $K$ and $K'$, and is shown in the inset of Fig 4. Two such combinations couple to electrons exactly in the same way as the two components of the Kekulé distortion

$$H_{e-ph,K} = F_K \int d^2r \psi^\dagger (M_1 u_{K1} + M_2 u_{K2}) \psi,$$ (3)

with $F_K = 3\hbar t/\beta a$. For this reason, this phonon is also known as the Kekulé phonon. The fact that the $E_2$ and $A_1$ phonons are the most predominant is confirmed by Raman spectroscopy in pristine graphene, where two main peaks are observed, the $G$ peak corresponds to $E_2$ phonons, while the $2D$ peak is a second-order process involving two $A_1$ phonons. The Hamiltonian of the $A_1$ phonon may be expressed as

$$H = \sum_i \int \frac{d^2q}{(2\pi)^2} \omega_K b_{i,q}^\dagger b_{i,q},$$ (4)

with creation and destruction operators defined by

$$u_i = \frac{A_c}{4\omega_K M} \int \frac{d^2q}{(2\pi)^2} (b_{i,q} e^{i\vec{q}\vec{r}} + b_{i,q}^\dagger e^{-i\vec{q}\vec{r}}).$$ (5)

where $i = K1, K2$, $\omega_K \approx 0.17$ eV, $A_c$ is the unit cell area. For the range of momenta $q < 0.25 \, \text{Å}^{-1}$ where the Dirac fermion model is applicable, the dispersion of the phonon can be neglected. Indeed, phonon band-structure computations excluding the effect of electron-phonon coupling show a practically flat dispersion in this range. A dimensionless EPC can be defined as

$$\lambda_K = F_K^2 A_c / (2M_0 \omega K v^2),$$ (6)

which is estimated to be in the range $\lambda_K \approx 0.03$–0.1.

Due to electron-phonon interactions, phonon dispersion relations are known to develop nonanalytic points, known as Kohn anomalies, at the largest momenta for which the generation of an electron-hole excitation is kinematically allowed. This renormalization of the dispersion, as well as the phonon lifetime, can be obtained from the phonon self-energy $\Sigma$, which enters in the phonon Green’s function as

$$G_{ph}(\omega,q) = \frac{2\omega_K}{\omega^2 - \omega_K^2 - 2\omega_K \Sigma(\omega,q)}.$$ (7)

As anticipated, this self-energy is related to the mass susceptibility, which is defined as

$$\Pi_{nm} = \langle \psi^\dagger M_n \psi \psi^\dagger M_m \psi \rangle$$ (8)

because of the form of the coupling given in Eq. (3). The explicit relation follows from the previous definitions and reads as

$$\Sigma = \frac{\lambda_K}{2} \Pi_{11} = \frac{\lambda_K}{2} \Pi_{22}.$$ (9)

In the absence of electron-electron interactions, the self-energy can be computed analytically, and it is given by

$$\Sigma(\omega,q) = \frac{\lambda_K}{4} (v^2 q^2 - \omega^2)^{1/2}.$$ (10)

Solving for the pole in Eq. (7) for small $\lambda_K$, we see the dispersion relation is corrected to

$$\omega(q) \approx \omega_K + \lambda_K / 4(v^2 q^2 - \omega^2)^{1/2},$$ (11)

which has a square-root singularity at $q_K$ for $q > q_K$. For $q < q_K$, the self-energy is purely imaginary, and a finite lifetime is obtained. The Kohn anomaly is conventionally associated with a linear cusp in the dispersion, which is obtained only asymptotically for $q \gg q_K$: the full dynamical self-energy should be used in general. Note that $q_K$ is approximately 2% of the $\Gamma - K$ distance in the Brillouin zone. The necessity of employing the dynamical self-energy has been emphasized before, in particular in the doped case where the static approximation produces poor agreement with experiments.

III. POWER-LAW MASS SUSCEPTIBILITY AND PHONON DISPERSION

We will now proceed to compute the general $\omega$- and $q$-dependent mass susceptibility $\Pi_{nm}$ including the Coulomb interaction. We will see that it acquires $\beta$-dependent power-law behavior, a feature that is thus inherited by the $A_1$ phonon. We will employ a ladder summation, as it is the simplest approximation that will capture any nonanalytic behavior.
ladder summation is represented diagrammatically in Fig. 1. Denoting three-momenta \( q = (q_0, \vec{q}) \), one has

\[
\Pi_{nm}(q) = 2i \int \frac{d^3p}{(2\pi)^3} \text{tr}[M_n G(p) \Gamma_m(p, p + q) G(p + q)],
\]

where the mass vertex \( \Gamma_m \) is a \( 4 \times 4 \) matrix (the sublattice/valley index is omitted for clarity), and the factor of 2 accounts for spin. In the ladder approximation, \( \Gamma_m \) satisfies the self-consistent equation

\[
\Gamma_m(p, q) = M_m + i e^2 \int \frac{d^3k}{(2\pi)^3} \frac{G(k) \Gamma_m(k, q) G(k + q)}{|\vec{p} - \vec{k}|},
\]

where \( v_F = 1 \) henceforth

\[
G(k) = \frac{k_0 + \vec{a} \vec{k}}{k_0^2 - \vec{k}^2 + i\epsilon}.
\]

To solve this set of equations, it is convenient to decompose \( \Gamma_m \) in a basis of \( 4 \times 4 \) matrices with well-defined transformation properties under the SU(2) valley symmetry. Defining \( \tilde{\Gamma} \), this basis may be taken as the four matrices \( \tilde{M}, \tilde{\mathcal{I}}, \tilde{\alpha} \), which are scalars under this symmetry, and the matrices \( M_n, T_n, \alpha T_n \), which transform like a spin 1/2. With this choice, we express \( \Gamma_m \) as

\[
\Gamma_m = \tilde{\Gamma} \tilde{M} + \tilde{\Gamma} \tilde{\mathcal{I}} \tilde{\alpha} + \tilde{\Gamma} \tilde{\alpha} T_n + \tilde{\Gamma} \tilde{\alpha} T_n.
\]

The equations are further simplified when \( \Gamma_{nm}^i \) is expressed in terms of its longitudinal and transverse parts

\[
\Gamma_{nm}^L = \tilde{q} \cdot \tilde{\Gamma}_{nm}, \quad \Gamma_{nm}^T = \tilde{\tilde{q}} \times \tilde{\Gamma}_{nm},
\]

where \( \tilde{q} = q / q \), and a similar relation applies for \( \tilde{\Gamma}_{nm}^i \). With the identities

\[
\tilde{\tilde{q}} \cdot \tilde{\Gamma}_{nm} = \tilde{\tilde{q}} \cdot \tilde{\Gamma}_{nm}^L - \tilde{\tilde{q}} \times \tilde{\tilde{q}} \tilde{\Gamma}_{nm}^T, \quad \tilde{\tilde{q}} \times \tilde{\Gamma}_{nm} = \tilde{\tilde{q}} \times \tilde{\Gamma}_{nm}^L + \tilde{\tilde{q}} \times \tilde{\tilde{q}} \tilde{\Gamma}_{nm}^T,
\]

by substituting Eq. (15) into (12), and performing the trace, we obtain

\[
\Pi_{nm}(q) = i \int \frac{d^3p}{(2\pi)^3} \frac{8}{D} \left[ f_{11} \Gamma_{nm}^L + f_{12} \Gamma_{nm}^T + \tilde{p} \times \tilde{q} \left( f_{13} \Gamma_{nm}^L + f_{14} \Gamma_{nm}^T \right) \right],
\]

where we have defined the denominator

\[
D(p, q) = [(p_0^2 - \vec{p}^2 + i\epsilon)(q_0^2 - \vec{q}^2)] - (\vec{p} + \vec{q})^2 + i\epsilon].
\]
momentum dependence, read as
\[
\Gamma^{(0,0)}(p,q) = 1 + \frac{\beta}{2p} \int_0^\Lambda dk \, C^{(0)}(k/p)K_{11}^{(0)}(k,q)\Gamma^{(0,0)}(k,q),
\]
where \(\Lambda\) is an ultraviolet cutoff regularizing the integrals. Note the product \(C^{(0)}(k/p)K_{11}^{(0)}(k,q)\) goes as \(p/k\) for \(k\) large, so the iteration of this equation produces a series of logarithms characteristic of power-law behavior. Also, note that when the external \(q < q_0\), all \(K_{ij}\) develop an imaginary part for \((q_0 - q)/2 < k < (q_0 + q)/2\).

We solve Eq. (31) numerically by discretizing the momentum \(k\) on a logarithmic mesh and solving the corresponding matrix equation by Gaussian elimination. The integration of Eq. (32) is straightforward. The result of this procedure is \(\Pi(q_0,q)\). It is convenient to represent it as the difference \(\Delta \Pi = \Pi(q_0,q_0 + \delta q) - \Pi(q_0,q_0)\) with \(\delta q = q_0 - q\). Figure 2 displays the real and imaginary parts of \(\Delta \Pi\) for \(|\delta q| \ll q_0\). We observe a cusp at \(\delta q = 0\) in the real part, and a finite imaginary part for \(\delta q < 0\). Log plots of both sides of the real and the imaginary parts reveal power laws as \(\delta q \to 0\). A Kramers-Kronig analysis for \(|\delta q| \ll q_0\) shows that this is only consistent if \(\Delta \Pi \propto (\delta q)^\eta\), i.e., the exponents are all the same. Figure 3 shows a log plot for \(\delta q > 0\) where power-law behavior is evident for \(\delta q < q_0\). We also observe that \(\Delta \Pi\) crosses over to a different power law for \(\delta q \gg q_0\), which we identify as the static result \(q^{\eta_0}\). The inset of Fig. 3 shows that \(\eta_0 = \eta_0 = \beta\) dependent, and that it tends to the noninteracting result in Eq. (10) as \(\beta \to 0\). The dependence of \(\eta_0\) on \(\beta\) can be found in Ref. 9.

Finally, we plot the phonon dispersion relation, which is the main result of this work. This is given in terms of the self-energy evaluated at the phonon frequency \(\omega_K\). To ease the comparison at different values of \(\beta\), we will also represent the difference
\[
\Delta \omega(q) = \omega(q) - \omega(q_K) = \frac{\lambda_K}{2} [\Pi(\omega_K,q) - \Pi(\omega_K,q_K)],
\]
where we have recovered physical units with \(\hbar v_F = 6.5\text{ eV Å}\). The values of the parameters used are \(\lambda_K = 0.1\) and \(\Lambda = 1.7\text{ eV}\). The phonon dispersion is depicted in Fig. 4 for different values of \(\beta\). The dispersion follows the static power law \(q^{\eta_0(\beta)}\) for \(q \gg q_K\), and the cusp turns into \(q^{\eta(\beta)}\) as discussed.

**FIG. 2.** (Color online) Mass susceptibility \(\Delta \Pi(q_0,q_0 + \delta q)\) for \(|\delta q| \ll q_0\) and \(\beta = 0.36\), real part (full line), and imaginary part (dashed line).

![Image 2](image2.png)

**FIG. 3.** (Color online) Logarithmic plot of the mass susceptibility \(\Delta \Pi(q_0,q_0 + \delta q)\) for \(\beta = 0.24\) and \(\delta q > 0\) (dotted line). The full lines are linear fits with \(\eta = 0.45\) for \(\delta q \ll q_K\) and \(\eta_0 = 0.69\) for \(\delta q > q_K\). Inset: The exponent \(\eta\) as a function of \(\beta\).

![Image 3](image3.png)

**FIG. 4.** (Color online) \(A_1\) phonon dispersion relation \(\Delta \omega(q)\) measured from the \(K\) point for \(\beta = 0.0,1,0.2,0.3\), with higher curves corresponding to higher values of \(\beta\). Note that \(\omega(q_K)\), which depends on \(\beta\), has been substracted from each curve for an easier comparison. Inset: the Kekulé phonon displacements.

**IV. DISCUSSION**

Our computation has shown that interactions turn the Kohn anomaly at the \(K\) point into a power law, so it is natural to ask whether the same effect happens for the anomaly at \(\Gamma\). This is not expected in general grounds because the corresponding self-energy is built with vertices corresponding to a conserved current, and these types of operators do not have anomalous dimensions because of Ward identities. This is also consistent with the fact that the Coulomb interaction...
renormalizes the $A_1$ electron-phonon coupling strongly, but not the $E_2$ one.\textsuperscript{21,23} Power-law behavior is thus only expected in the $K$-point anomaly.

From the experimental point of view, there are several techniques available for the measurement of the $A_1$ phonon dispersion, and each one has its own potential difficulties. In general, the power law at $q > q_K$ appears in a range of momenta that has been already probed with different techniques, while the cusp structure lies within the precision limits of current experiments, and may require more effort.

Electron energy loss spectroscopy (EELS) is, for example, a suitable technique that has already been used to map the phonon dispersion at the $K$ point in graphene. This experiments have been performed on different substrates for which graphene behaves as quasi-freestanding,\textsuperscript{16,30} such as Pt (this is important as hybridization with the substrate strongly changes the electron band structure and the Kohn anomaly\textsuperscript{31}). Metallic screening is, however, a disadvantage as it spoils the critical behavior of the electrons, and an insulating substrate would be more suited to observe the effect.

A more indirect experiment (with insulating substrate) is to track the dependence of the 2D Raman peak with incoming laser energy. This method has been used\textsuperscript{14} to measure the dispersion of the $A_1$ phonon. While the amount of data it yields and the range of momenta it covers is limited and not very close to the $K$ point, the observation of the $q > q_K$ regime is certainly possible. Finally, x rays are a usual tool to measure phonon dispersions in three-dimensional crystals, and while it is probably challenging to obtain enough intensity from a single sheet of graphene, experiments in graphite\textsuperscript{15,32} might be used to deduce the phonon dispersion. This approach is not straightforward because the electronic structure of graphite is different from graphene, and this must be taken into account. Nevertheless, it is encouraging to observe that precision measurements show an $A_1$ phonon dispersion that is not at all linear.\textsuperscript{15}

A final comment concerns the robustness of our result to more refined approximations schemes than the ladder summation. While other sets of diagrams may modify our quantitative predictions, it is very unlikely that the nonanalytic behavior can be removed in this way. One may consider, for example, the inclusion of self-energy terms for the electron propagator,\textsuperscript{3} which may produce a slow logarithmic dependence of the exponent. Finally, we also note that the $1/N$ approximation does give power-law behavior for the Kekulé mass correlator,\textsuperscript{10,11} (and thus the self-energy) as well.

In summary, this work has shown that the elusive critical behavior of interacting Dirac electrons in graphene manifests itself through a power-law Kohn anomaly for the $A_1$ phonon at the $K$ point.
