rescattering and P-wave π and ρ rescattering terms. The former is described in terms of S-wave πN scattering amplitudes with parametrization to include σ, ρ and hard core contributions. The latter is related to intermediate nucleon-pole and Δ-isobar propagations, and non-static contributions are also included. The rest of the higher-order terms are treated as distortions via π-nucleus and proton-nucleus optical potentials.

To test this picture, the model will be applied initially to (p,π^+) reactions on closed shell target nuclei leading to single-particle and 2p-1h states in the residual nucleus.

Recent experimental[1,2,3] and theoretical[4] studies of pion production with complex projectiles have emphasized the importance of further study of reactions such as $(^3He,\pi)$ at energies well below the free nucleon-nucleon pion production threshold in order to test for collective effects in pion production. Bertsch[4] has calculated the $(^3He,\pi)$ reaction cross section at 70 MeV/nucleon (which is zero, neglecting collective effects). By including the internal momentum of the ^3He nucleons, he calculated ~1 nanobarn total cross section. Wall et al.[1] have measured the $^{208}Pb(^3He,\pi^0)^{211}Po$ cross section for 200 MeV ^3He to be 6.0×10^{-2} nb/sr-MeV, yielding a total cross section of 2.4 nb (with a factor of 3 uncertainty). Doubly coherent production[2] of π^- by 910 MeV ^3He ions on ^6Li yielded a double differential cross section of $(0.42\pm0.11)\times10^{-3}$ nb/sr-MeV, or a total cross section of about 1.2 nb. Apparently the total doubly coherent cross section increases little with increasing energy.

In the present investigation Astatine was radiochemically separated[5] from the 10-100 mg/cm^2 activated Pb metal or nitrate targets in separation times of 1-3 hours and finally deposited electrochemically onto Ag foils. The sources from both thick (100 mg/cm^2) and thin (10 mg/cm^2) targets were α-counted using standard α-spectroscopy. Tentative results for the excitation function for the production of Astatine isotopes is given in Table 1. The below-threshold measurement gave an upper limit of 0.1 nb, indicating little secondary background problem. Above the π^- threshold of 134.8 MeV, the cross section

Table 1. Measured Astatine cross sections produced in 130-230 MeV ^3He on ^{208}Pb.

^3He Energy (MeV)	σ(207) (nanobarns)	σ(211) (nanobarns)	Target Thickness (mg/cm^2)
130	<0.1	<0.1	10
158	13	3.4	63
200	10	6.6	71
230	<2.5	2.5	75

Total uncertainties include chemical yield (40%), beam integration (5%), statistics (30%) and target thickness (5%), yielding in quadrature a total error of 50%.

was measured in the 1-10 nb range, in agreement with previous results of Ref. 1 and 2.

Future runs are planned at ^{3}He energies of 270 MeV and between 130 and 200 MeV to search for the threshold effect.

The total reaction cross section for the ^{209}Bi(p,γ+π°)^{210}Po reaction was measured in the energy range of 62-200 MeV at IUCF and 183-480 MeV at TRIUMF. The measurements were made using activation techniques and radio chemistry with α- and γ-ray spectroscopy. The excitation function, σ(E), for the combined (p,γ+π°) cross section hovers at the 1-10 μb level in this intermediate energy range as shown in Figs. 1a and 1b. In Fig. 1a the absolute total cross sections are plotted with an error of ~30%. These errors are due to the chemical yield determination (20%), beam intergration (5%), detection solid angle (5%), counting statistics (10%) and target thickness (5%). Renormalization to the (p,2n) product significantly reduces the overall uncertainty to a relative 12% uncertainty due mainly to statistics.

Below pion threshold (130.7 MeV) the radiative proton capture cross section decreases logarithmically with a $1/E^{2.12}$ dependence. Subtracting out the (p,γ) contribution, the residual (p,π°) cross section is shown in Fig. 2. Near the neutral pion threshold (below the neutron binding energy), the cross
